A Guided Tour of Chapter 7: Derivatives Pricing and Hedging

Ashwin Rao

ICME, Stanford University

February 9, 2021

Brief Overview of Derivatives

- Term Derivative comes from the word Derived
- Financial product whose structure (and hence, *value*) is derived from the *performance* of an *underlying* entity
- Technically a legal contract between buyer and seller that is either:
 - Lock-type: Entitles buyer to future contingent-cashflow (payoff)
 - Option-type: Buyer has future choices, leading to contingent-cashflow
- Some common derivatives:
 - Forward Contract to deliver/receive asset on future date for fixed cash

Forward Payoff:
$$f(X_t) = X_t - K$$

- European Option Right to buy/sell on future data at agreed price
 - Call and Put Option Payoff: $\max(X_t K, 0)$ and $\max(K X_t, 0)$
- American Option Can exercise option on any day before expiration
- Why do we need derivatives?
 - To protect against adverse market movements (risk-management)
 - To express a market view *cheaply* (leveraged trade)

Derivatives Pricing and Hedging problems as MDPs

- Pricing: Determination of fair value of an asset or derivative
- Hedging: Protect against market movements with "opposite" trades
- Replication: Clone payoff of a derivative with trades in other assets
- We consider two applications of Stochastic Control here:
 - Optimal Exercise of American Options in an idealized setting
 - Optimal Hedging of Derivatives Portfolio in a real-world setting
- Both problems enable us to price the respective derivatives
- Expressing these problems as MDP Control brings ADP/RL into play
- Optimal Exercise of American Options is Optimal Stopping problem
- So we start by learning about Stopping Time and Optimal Stopping

Stopping Time

- ullet Stopping time au is a "random time" (random variable) interpreted as time at which a given stochastic process exhibits certain behavior
- Stopping time often defined by a "stopping policy" to decide whether to continue/stop a process based on present position and past events
- Random variable τ such that $Pr[\tau \leq t]$ is in σ -algebra \mathcal{F}_t , for all t
- ullet Deciding whether $au \leq t$ only depends on information up to time t
- Hitting time of a Borel set A for a process X_t is the first time X_t takes a value within the set A
- Hitting time is an example of stopping time. Formally,

$$T_{X,A} = \min\{t \in \mathbb{R} | X_t \in A\}$$

eg: Hitting time of a process to exceed a certain fixed level

Optimal Stopping Problem

• Optimal Stopping problem for Stochastic Process X_t :

$$W(x) = \max_{\tau} \mathbb{E}[H(X_{\tau})|X_0 = x]$$

where τ is a set of stopping times of X_t , $W(\cdot)$ is called the Value function, and H is the Reward function.

- Note that sometimes we can have several stopping times that maximize $\mathbb{E}[H(X_{\tau})]$ and we say that the optimal stopping time is the smallest stopping time achieving the maximum value.
- Example of Optimal Stopping: Optimal Exercise of American Options
 - ullet X_t is risk-neutral process for underlying security's price
 - x is underlying security's current price
 - ullet au is set of exercise times corresponding to various stopping policies
 - ullet $W(\cdot)$ is American option price as function of underlying's current price
 - $H(\cdot)$ is the option payoff function, adjusted for time-discounting

Optimal Stopping Problems as Markov Decision Processes

- We formulate Stopping Time problems as Markov Decision Processes
- State is X_t
- Action is Boolean: Stop or Continue
- Reward always 0, except upon Stopping (when it is $=H(X_{\tau})$)
- State-transitions governed by the Stochastic Process X_t
- For discrete time steps, the Bellman Optimality Equation is:

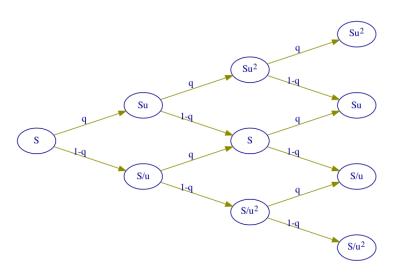

$$V^*(X_t) = \max(H(X_t), \mathbb{E}[V^*(X_{t+1})|X_t])$$

• For finite number of time steps, we can do a simple backward induction algorithm from final time step back to time step 0

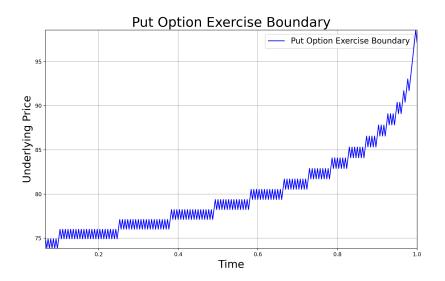

Mainstream approaches to American Option Pricing

- American Option Pricing is Optimal Stopping, and hence an MDP
- So can be tackled with Dynamic Programming or RL algorithms
- But let us first review the mainstream approaches
- For some American options, just price the European, eg: vanilla call
- When payoff is not path-dependent and state dimension is not large, we can do backward induction on a binomial/trinomial tree/grid
- Otherwise, the standard approach is Longstaff-Schwartz algorithm
- Longstaff-Schwartz algorithm combines 3 ideas:
 - Valuation based on Monte-Carlo simulation
 - Function approximation of continuation value for in-the-money states
 - Backward-recursive determination of early exercise states
- RL is an attractive alternative to Longstaff-Schwartz algorithm

Binomial Tree for Backward Induction

Optimal Exercise Boundary of American Put Option

Classical Pricing and Hedging of Derivatives

- Classical Pricing/Hedging Theory is based on a few core concepts:
 - Arbitrage-Free Market where you cannot make money from nothing
 - Replication when the payoff of a *Derivative* can be constructed by assembling (and rebalancing) a portfolio of the underlying securities
 - Complete Market where payoffs of all derivatives can be replicated
 - Risk-Neutral Measure Altered probability measure for movements of underlying securities for mathematical convenience in pricing
- Assumptions of arbitrage-free and completeness lead to (dynamic, exact, unique) replication of derivatives with the underlying securities
- Assumptions of frictionless trading provide these idealistic conditions
- Frictionless := continuous trading, any volume, no transaction costs
- Replication strategy gives us the pricing and hedging solutions
- This is the foundation of the famous Black-Scholes formulas.
- However, the real-world has many frictions ⇒ Incomplete Market
- ... where derivatives cannot be exactly replicated

Pricing and Hedging in an Incomplete Market

- In an incomplete market, we have multiple risk-neutral measures
- So, multiple derivative prices (each consistent with no-arbitrage)
- The market/trader "chooses" a risk-neutral measure (hence, price)
- This "choice" is typically made in ad-hoc and inconsistent ways
- Alternative approach is for a trader to play Portfolio Optimization
- Maximizing "risk-adjusted return" of the derivative plus hedges
- Based on a specified preference for trading risk versus return
- This preference is equivalent to specifying a Utility function
- Reminiscent of the Portfolio Optimization problem we've seen before
- Likewise, we can set this up as a stochastic control (MDP) problem
- Where the decision at each time step is: Trades in the hedges
- So what's the best way to solve this MDP?

Deep Reinforcement Learning (DRL)

- Dynamic Programming not suitable in practice due to:
 - Curse of Dimensionality
 - Curse of Modeling
- So we solve the MDP with *Deep Reinforcement Learning* (DRL)
- The idea is to use real market data and real market frictions
- Developing realistic simulations to derive the optimal policy
- The optimal policy gives us the (practical) hedging strategy
- The optimal value function gives us the price (valuation)
- Formulation based on <u>Deep Hedging paper</u> by J.P.Morgan researchers
- More details in the <u>prior paper</u> by some of the same authors

Problem Setup

- We will simplify the problem setup a bit for ease of exposition
- This model works for more complex, more frictionful markets too
- Assume time is in discrete (finite) steps t = 0, 1, ..., T
- Assume we have a position (portfolio) D in m derivatives
- Assume each of these m derivatives expires in time $\leq T$
- ullet Portfolio-aggregated *Contingent Cashflows* at time t denoted $X_t \in \mathbb{R}$
- Assume we have n underlying market securities as potential hedges
- Hedge positions (units held) at time t denoted $\alpha_t \in \mathbb{R}^n$
- ullet Cashflows per unit of hedges held at time t denoted $Y_t \in \mathbb{R}^n$
- Prices per unit of hedges at time t denoted $P_t \in \mathbb{R}^n$
- PnL position at time t is denoted as $\beta_t \in \mathbb{R}$

States and Actions

- ullet Denote state space at time t as \mathcal{S}_t , state at time t as $s_t \in \mathcal{S}_t$
- Among other things, s_t contains $\alpha_t, P_t, \beta_t, D$
- ullet s_t will include any market information relevant to trading actions
- For simplicity, we assume s_t is just the tuple $(\alpha_t, P_t, \beta_t, D)$
- Denote action space at time t as \mathcal{A}_t , action at time t as $a_t \in \mathcal{A}_t$
- \bullet a_t represents units of hedges traded (positive for buy, negative for sell)
- ullet Trading restrictions (eg: no short-selling) define \mathcal{A}_t as a function of s_t
- State transitions $P_{t+1}|P_t$ available from a *simulator*, whose internals are estimated from real market data and realistic assumptions

Sequence of events at each time step t = 0, ..., T

- **①** Observe state $s_t = (\alpha_t, P_t, \beta_t, D)$
- 2 Perform action (trades) a_t to produce trading $PnL = -a_t \cdot P_t$
- **3** Trading transaction costs, example $= -\gamma P_t \cdot |a_t|$ for some $\gamma > 0$
- Update α_t as: $\alpha_{t+1} = \alpha_t + a_t$ (force-liquidation at termination means $a_T = -\alpha_T$)
- **3** Realize cashflows (from updated positions) = $X_{t+1} + \alpha_{t+1} \cdot Y_{t+1}$
- **1** Update PnL β_t as:

$$\beta_{t+1} = \beta_t - a_t \cdot P_t - \gamma P_t \cdot |a_t| + X_{t+1} + \alpha_{t+1} \cdot Y_{t+1}$$

- **Q** Reward $r_t = 0$ for all t = 0, ..., T 1 and $r_T = U(\beta_{T+1})$ for an appropriate concave Utility function U (based on risk-aversion)
- **Simulator** evolves hedge prices from P_t to P_{t+1}

Pricing and Hedging

- Assume we now want to enter into an incremental position (portfolio) D' in m' derivatives (denote the combined position as $D \cup D'$)
- We want to determine the *Price* of the incremental position D', as well as the hedging strategy for D'
- ullet Denote the Optimal Value Function at time t as $V_t^*:\mathcal{S}_t o\mathbb{R}$
- Pricing of D' is based on the principle that introducing the incremental position of D' together with a calibrated cashflow (Price) at t=0 should leave the Optimal Value (at t=0) unchanged
- Precisely, Price of D' is the value x such that

$$V_0^*((\alpha_0, P_0, \beta_0 - x, D \cup D')) = V_0^*((\alpha_0, P_0, \beta_0, D))$$

- This Pricing principle is known as the principle of Indifference Pricing
- The hedging strategy at time t for all $0 \le t < T$ is given by the Optimal Policy $\pi_t^* : \mathcal{S}_t \to \mathcal{A}_t$

DRL Approach a Breakthrough for Practical Trading?

- The industry practice/tradition has been to start with Complete Market assumption, and then layer ad-hoc/unsatisfactory adjustments
- There is some past work on pricing/hedging in incomplete markets
- But it's theoretical and not usable in real trading (eg: Superhedging)
- My view: This DRL approach is a breakthrough for practical trading
- Key advantages of this DRL approach:
 - Algorithm for pricing/hedging independent of market dynamics
 - ullet Computational cost scales efficiently with size m of derivatives portfolio
 - Enables one to faithfully capture practical trading situations/constraints
 - Deep Neural Networks provide great function approximation for RL
